Objective: intermittent pneumatic compression (IPC) of the foot (IPC\textsubscript{foot}), calf (IPC\textsubscript{calf}) or both (IPC\textsubscript{foot+calf}) augments calf inflow, and improves the walking ability and peripheral haemodynamics of claudicants (IPC\textsubscript{foot}, IPC\textsubscript{foot+calf}), largely due to venous outflow enhancement. This cohort study, using direct pressure measurements in healthy limbs, determines the optimal combination of frequency (2-4 impulses/minute), applied pressure (60-140mmHg), mode (IPC\textsubscript{foot} - IPC\textsubscript{calf} - IPC\textsubscript{foot+calf}) and delay time of calf-to-foot impulse (0 s-0.5 s-1 s) that enables IPC to generate an almost complete and sustained decrease in venous pressure.

Results: (a) IPC\textsubscript{foot} at 120 and 80mmHg generated lower venous pressure than that with 100 and 60mmHg (p = 0.036) respectively, for 2-4 impulses/minute; venous pressure differences between applied pressures of 140 and 120mmHg or between 80 and 100mmHg were insignificant. (b) Venous pressure with IPC\textsubscript{calf} at 80mmHg was lower than that with 60mmHg (p = 0.036) (2-4 cycles/minute); differences in venous pressure between applied pressures of 140 and 100 mmHg or between 120 and 80mmHg were insignificant. (c) At applied pressures 60-140mmHg, IPC\textsubscript{foot+calf} with one-second delay generated lower venous pressure than that with half-second delay (p = 0.036), the latter being more efficient than zero delay; increasing applied pressures produced lower venous pressure, but differences were small. Venous pressure decreased with increasing IPC frequency (from 2 to 3-4/minute), at applied pressures 60-140mmHg.

Conclusions: IPC\textsubscript{foot+calf} at applied 120-140mmHg, a frequency of 3-4 impulses/minute and one-second delay, provided the optimum intermittent pneumatic stimulus.
